

The propagated ground covariance is calibrated because it carries TWO terms: mean NEES 45.39 → 2.83 against an ideal of 2.0

(a) Σ_{yaw} is the whole calibration story: dropping it costs 5-13× in NEES, while the pixel term alone can never close the gap

(b) The deployed χ^2 gate (9.21) needs no change: 0.014 against a nominal 0.01

(c) And it is calibrated EVERYWHERE, not just on average: every range band, camera and yaw lands in 2.54-3.18

Strata are MARGINAL (one factor at a time), never crossed, and e4's summary records only the stratum mean — no per-stratum n or confidence interval. Cameras appear as strata, not as calibration terms: e6 showed the per-camera signal on the external driving logs is confounded with robot silhouette geometry and fixed route yaw, so no per-camera bias conclusion may be drawn from panel (c).
