

Measurement uncertainty is not constant across a camera footprint

(a) ACCURACY improves with distance
median error falls; near the camera is the most biased

(b) CONSISTENCY degrades with distance
spread roughly doubles — a single constant fits neither end

Baseline path: plain inverse perspective mapping, zero parameters (8301 clear detections, four cameras, eight robot headings, 2 m bins with at least 25 samples). Both trends hold on every camera independently, so they are properties of the viewing geometry rather than of one mount. Near the camera the steep view turns the silhouette offset into a large but repeatable ground error; far away the projection amplifies pixel noise into spread. Ground truth measures the error and never enters the projection.
